Zukule, R. Investigation of Electrodes and Electrolytes for Obtaining Amphoteric Decoupled Zn-MnO<sub>2</sub> Rechargeable Batteries. Summary of the Doctoral Thesis. – Riga: RTU Press, 2025. – 49 p.

Published in accordance with the decision of the Promotion Council “RTU P-02” of September 4, 2025, Minutes No. 04030-9.2/5.

The Doctoral Thesis was developed within the framework of the FLPP project “Investigation of electrodes and electrolytes for obtaining amphoteric decoupled rechargeable batteries” No. lzp-2021/1–0142.

This research was supported

- 1) by the European Social Fund within the Project No. 8.2.2.0/20/I/008 “Strengthening of PhD students and academic personnel of Riga Technical University and BA School of Business and Finance in the strategic fields of specialization” of the Specific Objective 8.2.2 “To Strengthen Academic Staff of Higher Education Institutions in Strategic Specialization Areas” of the Operational Programme “Growth and Employment”;

- 2) by Riga Technical University's Doctoral Grant programme.

## ACKNOWLEDGEMENTS

I express my deepest gratitude to all those who have supported and guided me throughout the entire doctoral journey.

First, I would like to extend my heartfelt thanks to my main supervisors, Dr. chem. Gunārs Bajārs and Dr. chem. Reinis Drunka, for their outstanding professional guidance and invaluable feedback. Their in-depth suggestions and constructive criticism significantly contributed to the creation of this Thesis.

I would also like to express sincere gratitude to Dr. phys. Pāvels Onufrijevs, who laid the foundation for both my academic and professional development. His competence, encouragement, and understanding attitude have served as a continuous source of inspiration.

I also appreciate the excellent collaboration with my research group colleagues – PhD Anzelms Zukuls and Ņikita Griščenko – for their support, cooperation, and the enriching discussions during the project development process. Together with my colleagues Mairis Iesalnieks, Linda Laima Alsiņa, and Mārtiņš Vanags, we have participated in many stimulating conversations that not only broadened our horizons but also helped us reach new peaks in our research.

I am equally grateful to the colleagues from the Institute of Physics and Materials Science, as well as to Dr. chem. Nelli Batenko and PhD Anastasija Gaile for their assistance and encouragement, which made my research experience both productive and truly exciting.

Finally, I would like to express my heartfelt gratitude to my life partner and family – whose unwavering love and boundless support were a true pillar throughout this journey. Their faith in me and emotional support were crucial in helping me maintain focus and motivation, even during the most challenging moments.

# **DOCTORAL THESIS PROPOSED TO RIGA TECHNICAL UNIVERSITY FOR PROMOTION TO THE SCIENTIFIC DEGREE OF DOCTOR OF SCIENCE**

To be granted the scientific degree of Doctor of Science (PhD), the present Doctoral Thesis has been submitted for defence at the open meeting of RTU Promotion Council “RTU P-02” on December 10, 2025, in an open meeting online on the Zoom platform: <https://rtucloud1.zoom.us/j/96283313764>; ID: 962 8331 3764.

# GENERAL OVERVIEW OF THE THESIS

## Introduction

Global demand for efficient and sustainable energy storage solutions continues to rise alongside the increasing use of renewable energy sources and the electrification of various sectors [1]–[5]. Renewable energy sources are characterized by irregular energy production – for example, solar energy can only be harnessed during daylight hours [6]–[8]. Therefore, batteries play a crucial role in mitigating the intermittency of renewables by ensuring reliable energy storage and a stable electricity supply on demand [9]–[12]. Currently, one of the most widespread and successful energy storage technologies is rechargeable lithium-ion batteries [13]–[17]. They offer high energy (up to 500 Wh/g) and power (up to 300 W/kg) densities, a large theoretical capacity (890 mA h/g), high operating voltage ( $> 3.7$  V), and excellent charge-discharge stability (over 10,000 cycles) with low self-discharge [18]–[24]. However, key drawbacks of rechargeable lithium-ion batteries include safety concerns due to overheating and potential self-ignition [25]–[29], as well as limited lithium resources [30]–[33]. These issues have prompted the search for alternatives by developing new or improving existing battery technologies.

Among existing battery technologies, aqueous electrolyte Zn-MnO<sub>2</sub> batteries have attracted considerable attention, as they already dominate the non-rechargeable battery market [34], [35]. They offer lower costs, higher safety, and are more environmentally friendly compared to chargeable lithium-ion batteries [36]–[38]. However, to meet future needs, it is necessary to develop their potential application as rechargeable batteries, which presents several challenges, such as electrolyte stability, electrode degradation, and performance limitations [19], [39]–[43].

One of the problems typical for rechargeable Zn-MnO<sub>2</sub> batteries is their low operating voltage and poor cyclability, stemming from the instability of the MnO<sub>2</sub> cathode and unwanted side reactions, such as MnO<sub>2</sub> disproportionation and dissolution, phase transitions to electrochemically inactive forms, oxygen evolution reaction (OER), and the formation of electrochemically inactive compounds with Zn<sup>2+</sup> ions [44], [45]. To optimize performance, various electrolyte compositions have been studied, including alkaline [19], [38], [46], [47], neutral [48]–[51], and acidic [52], [53] electrolytes. However, each approach undesirably affects cycle life, efficiency, and reaction kinetics. Further adaptation and exploration of electrolytes. i.e., creating pH gradient electrolytes and dual-electrolyte systems, offer significant improvements in electrochemical stability and operating voltage for Zn-MnO<sub>2</sub> systems. By carefully tailoring the electrolyte environment around the anode and cathode, it is possible to extend the electrochemical water decomposition window while mitigating side reactions [54]–[59].

In addition to electrolyte optimization, attention must be paid to the structural stability of the MnO<sub>2</sub> cathode. MnO<sub>2</sub> exists in several polymorphs, each with distinct electrochemical properties depending on its crystal structure. For the sequence  $\alpha > \delta > \beta$ , the theoretical capacity decreases, meaning the different phases exhibit varying cyclability and ion diffusion properties [60]–[62]. In alkaline electrolytes, the MnO<sub>2</sub> cathode may form electrochemically inactive phases such as Mn(OH)<sub>2</sub>, Mn<sub>2</sub>O<sub>3</sub>, and Mn<sub>3</sub>O<sub>4</sub> [19], while in acidic environments, it may

dissolve or transition into another polymorph due to side reactions [40], [63], leading to capacity loss. Introducing heteroatoms into the electrode structure is a potential solution to improve electrochemical properties [64]. Studies have explored the effects of heteroatoms on MnO<sub>2</sub> in alkaline and neutral electrolytes. For example, doping with Co [65]–[67] and Mo [68], [69] promotes defect formation in the MnO<sub>2</sub> crystal lattice, stabilizing certain polymorphs. Meanwhile, Bi doping [34], [70]–[73] narrows the MnO<sub>2</sub> bandgap and facilitates electrochemical dissolution–deposition processes

Another key limitation of aqueous Zn-ion batteries is the instability of the metallic Zn anode, which leads to dendrite formation, hydrogen evolution reaction (HER), and surface passivation [41]–[43]. To prevent these side reactions, various surface modification methods have been explored to improve the electrochemical properties of Zn anodes. The main approaches include surface coating and electrolyte modification to control the Zn deposition–dissolution reactions. Coating types include CaCO<sub>3</sub> [74], ZnO [75]–[77], ZrO<sub>2</sub> [78]–[80], TiO<sub>2</sub> [81]–[83], and various polymer coatings [84]–[87].

Further development of this research, which includes electrolyte development, cathode stabilization, Zn surface modification, and integration into batteries, is an important step towards the commercialization of rechargeable aqueous electrolyte Zn-MnO<sub>2</sub> batteries. Therefore, this Doctoral Thesis focuses on the main limitations at the electrolyte, cathode, and anode levels with the aim of advancing rechargeable batteries with higher energy density, better cyclability, and improved safety.

## Aims and objectives

This Doctoral Thesis aims to develop a concept of increasing the voltage of aqueous Zn-MnO<sub>2</sub> batteries above 2 V and to investigate the required modifications to the electrolyte, cathode, and anode to realize this concept.

To achieve this aim, the following objectives were set:

1. Develop a strategy for increasing the operating voltage of water-based electrolyte rechargeable batteries above 2 V, bypassing the water decomposition voltage limitations.
2. To synthesize MnO<sub>2</sub> powders doped with Bi and Mo ions. To evaluate the properties of the obtained materials using non-destructive analytical methods and prepare thin coatings on carbon paper. To conduct electrochemical measurements of the prepared coatings in an acidic electrolyte solution.
3. To modify Zn plates using pulsed laser irradiation at different energy fluencies. To characterize the prepared samples using non-destructive analysis and perform electrochemical measurements in an alkaline electrolyte solution.
4. To create a pH gradient electrolyte using Pluronic F-127 hydrogel. To assemble a Zn-MnO<sub>2</sub> battery using the pH-gradient electrolyte, conduct electrochemical measurements, and determine whether the operating voltage window of the aqueous electrolyte can be extended beyond 2 V.

## **Thesis statements to be defended**

1. A pH gradient electrolyte system, where there is an alkaline environment at the anode and an acidic environment at the cathode, increases the electrochemical window of water.
2. Doping the MnO<sub>2</sub> cathode with Bi<sup>3+</sup> and Mo<sup>6+</sup> ions improves electrochemical performance in acidic electrolyte.
3. The stability of the Zn anode in an alkaline electrolyte is improved by structuring the anode surface with a pulsed laser.
4. A rechargeable amphoteric aqueous electrolyte Zn-MnO<sub>2</sub> battery can be created using Pluronic F-127 micelle-type hydrogel.
5. An aqueous electrolyte Zn-MnO<sub>2</sub> battery with a voltage above 2 V can be obtained by using two different pH electrolytes, or amphoteric systems.

## **Scientific novelty**

In the Doctoral Thesis, an innovative approach to the design of an aqueous Zn-MnO<sub>2</sub> rechargeable battery has been developed and implemented, thus overcoming fundamental limitations at the electrode and electrolyte levels. The study combines strategies in electrode material modification, electrolyte engineering, and battery design improvement to expand the operating voltage range of the battery and improve electrochemical performance. Research has been conducted to improve the stability and electrochemical performance of materials in different pH electrolyte environments, and a new battery concept has been developed based on separated cathode and anode electrolyte spaces. The results of the study reflect the relationships between the structure and properties of water-based electrolyte battery components, which can be used in the development of alternative energy storage systems.

## **Practical significance**

1. Development of aqueous electrolyte Zn-MnO<sub>2</sub> rechargeable batteries with increased operating voltage to promote the development of safer and more efficient alternative energy storage systems.
2. Development of a dual electrolyte system concept that reduces parasitic reactions on the electrodes, thereby improving electrochemical stability, as an alternative to traditional battery designs.
3. Development of scalable methods (doping of semiconductors with heteroatoms via the hydrothermal method and structuring of metal surfaces with a pulsed laser) for modifying electrodes that increase specific capacity.
4. Construction of rechargeable batteries using elements commonly found in the Earth's crust as electrode materials, creating an alternative battery technology that does not depend on critical raw materials.

## Structure and volume of the Thesis

The Doctoral Thesis is presented as a thematically unified collection of scientific publications focused on the development of an amphoteric aqueous Zn-MnO<sub>2</sub> battery and the individual improvement of its electrolyte and electrodes. The Thesis includes four original research articles and one review article published in Scopus-indexed journals.

## Publications and approbation of the Thesis

The main results of the Thesis are published in four scientific research articles. One review article was also prepared during the development of the Thesis. The research results have been presented at 17 scientific conferences.

# LITERATURE REVIEW AND RESULTS

Literature review and results of the Doctoral Thesis are presented in four main chapters, which combine one review article and four original publications:

1. Literature review on the performance of an aqueous electrolyte Zn-MnO<sub>2</sub> battery depending on the pH of the electrolyte medium, as well as an evaluation and explanation of the dual battery concept, summarizing the review article (Appendix 1).
2. Results of the research on improving the operation and performance of MnO<sub>2</sub> cathode in a highly acidic electrolyte by incorporating Bi and Mo ions into the MnO<sub>2</sub> structure, summarized in original Publication 1 (Appendix 2) and original Publication 2 (Appendix 3).
3. Results of the research on improving the operation and performance of Zn anode in alkaline electrolyte using surface structuring with a high-power pulsed laser, summarized in original Publication 3 (Appendix 4).
4. Results of the research on the development and electrochemical parameters of a dual aqueous electrolyte Zn-MnO<sub>2</sub> rechargeable battery, summarized in original Publication 4 (Appendix 5).

## 1. Literature review on the performance of an aqueous electrolyte Zn-MnO<sub>2</sub> battery depending on the pH of the electrolyte medium

The origins of aqueous electrolyte Zn-MnO<sub>2</sub> batteries date back to 1866, when French scientist Georges Leclanché manufactured and patented the first Zn-MnO<sub>2</sub> non-rechargeable battery, called the Leclanché cell [7]. These batteries were further developed in the 1950s by Canadian engineer Lewis Urry, who patented the alkaline Zn-MnO<sub>2</sub> battery in 1960 [88]–[91]. These batteries are still being improved, trying to extend their effective lifespan and replace hazardous elements such as mercury. Thus, aqueous alkaline Zn-MnO<sub>2</sub> batteries are the longest-standing and most widely used non-rechargeable battery technology, still dominating the global market [92]. This could be due to the fact that aqueous electrolyte Zn-MnO<sub>2</sub> batteries do not pose major safety risks, Zn metal has low toxicity (LD50 = 630 mg/kg – in rats) [93], Zn<sup>2+</sup>/Zn two-electron reaction has a relatively high theoretical capacity of 820 mAh/g [36], [37], as well as the theoretical capacity of MnO<sub>2</sub>/Mn<sup>2+</sup> two-electron reaction is 617 mAh/g [38], [94], [95]. Moreover, both zinc and manganese are common elements in the Earth's crust [36], [37].

### 1.1. Alkaline electrolyte Zn-MnO<sub>2</sub> batteries

An aqueous alkaline Zn-MnO<sub>2</sub> battery consists of a Zn metal anode, a MnO<sub>2</sub> cathode, and a concentrated KOH aqueous solution (> 30 %) electrolyte. Carbon black (CB) particles are usually added to the cathode to ensure its conductivity, as MnO<sub>2</sub> itself is non-conductive. The schematic of this non-rechargeable battery is shown in Fig. 1.1, where the Zn anode undergoes electrochemical Reaction (1) with a standard potential of –1.199 V, while the cathode active component MnO<sub>2</sub> undergoes Reactions (2) and (3) with a standard potential of +0.250 V. Thus,

overall Reaction (4) occurs in the alkaline battery, resulting in an OCV of 1.45 V for the battery [6], [94], [96], [97].

Overall reaction:

Alkaline Zn-MnO<sub>2</sub> batteries are a long-established technology and are still being researched. Although these batteries are widespread as non-rechargeable batteries, they are still not widespread as rechargeable batteries. This is mainly due to the formation of electrochemically inactive manganese oxides Mn<sub>3</sub>O<sub>4</sub> and ZnMn<sub>2</sub>O<sub>4</sub>. These compounds are formed during the deep discharge process [88], [98]. Thus, during the first few discharge-charge cycles, electrochemically inactive compounds cover the particles of the active MnO<sub>2</sub> compound of the cathode, stopping further reaction, which rapidly reduces the battery capacity. The scientific literature describes various ways to reduce or eliminate this undesirable effect in alkaline electrolytes, for example, doping the MnO<sub>2</sub> cathode with Bi or Cu ions [94], [99], as well as modifying the electrolyte by adding extra ions [100]–[102], such as Li<sup>+</sup> [98].

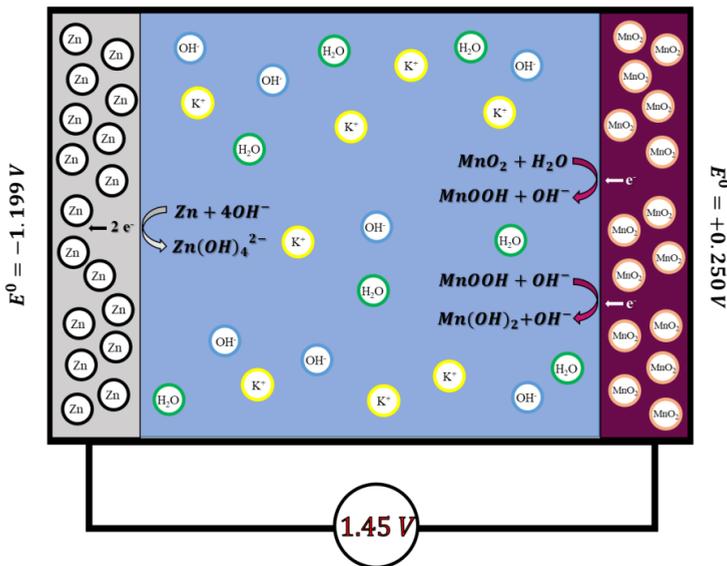

Fig. 1.1. Schematic operating mechanism of Zn-MnO<sub>2</sub> batteries with an alkaline aqueous electrolyte.

## 1.2. Neutral and acidic electrolyte Zn-MnO<sub>2</sub> batteries

The modification of the electrolyte in Zn-MnO<sub>2</sub> batteries has been further advanced by reducing the pH of the electrolyte from alkaline to neutral and even acidic, thereby altering the overall reactions occurring in the battery, as illustrated in the schematic representation of the Zn-MnO<sub>2</sub> battery with an acidic aqueous electrolyte (Fig. 1.2). In these systems, the alkaline electrolyte composed of KOH, NaOH, and LiOH [97], [98], [103]–[105] has been replaced with solutions of ZnSO<sub>4</sub>, MnSO<sub>4</sub>, K<sub>2</sub>SO<sub>4</sub>, Na<sub>2</sub>SO<sub>4</sub> [106]–[111] and/or a diluted acid electrolyte [52], [53]. As shown in the Pourbaix diagram of manganese compounds (Fig. 1.3 a), which depicts the changes in the standard potential of the element in an aqueous electrolyte depending on the pH, at higher pH values, the electrochemical reaction of MnO<sub>2</sub> occurs at a standard potential of 0.250 V, with the possibility of forming the electrochemically inactive Mn<sub>2</sub>O<sub>3</sub> phase. However, when the electrolyte pH is lowered to an acidic level, the oxygen atom in the MnO<sub>2</sub> cathode can bind with H<sup>+</sup> ions from the electrolyte, forming water molecules. Consequently, Mn<sup>4+</sup> ions can be reduced to Mn<sup>2+</sup> ions, which dissolve into the electrolyte solution without forming the electrochemically inactive Mn<sub>2</sub>O<sub>3</sub> phase. Moreover, this MnO<sub>2</sub> reaction in an acidic medium occurs at a standard potential above 1.2 V. However, this reduction in electrolyte pH increases the electrochemical reaction potential of the Zn anode. As seen in the Pourbaix diagram of zinc compounds (Fig. 1.3 b), the standard potential of the reaction increases from –1.199 V in an alkaline medium to –0.762 V in an acidic medium.

Despite the increase in the standard potential of the Zn anode, the overall battery design results in a higher operating voltage of up to 2 V, according to Reactions (5)–(7) [112]:

Overall reaction:

However, in an acidic medium, a parasitic reaction occurs – Zn anode corrosion. During this process, the Zn anode dissociates into Zn<sup>2+</sup> ions in the electrolyte, releasing H<sub>2</sub> gas. This parasitic reaction not only reduces the capacity of the battery but can also lead to the rupture of the battery cell [113]. The occurrence of the parasitic reaction at the anode can be mitigated by coating the Zn anode with fumed silica and polyethylene glycol (with a molecular weight of 300 g/mol) [114]. To prevent potential MnO<sub>2</sub> dissolution, 0.1 M MnSO<sub>4</sub> is added to the electrolyte [107]–[110]. However, even in this type of battery, the formation of the ZnMn<sub>2</sub>O<sub>4</sub> phase has been observed, which is chemically inactive and leads to capacity fading by increasing reaction irreversibility [115]. This suggests that both alkaline and neutral-acidic aqueous electrolyte Zn-MnO<sub>2</sub> batteries face similar challenges.

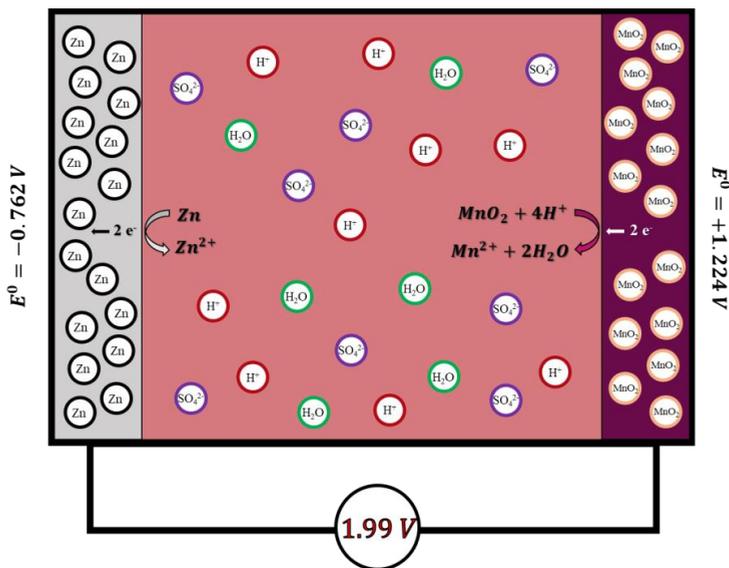

Fig. 1.2. Schematic operating mechanism of Zn-MnO<sub>2</sub> batteries with an acidic aqueous electrolyte.

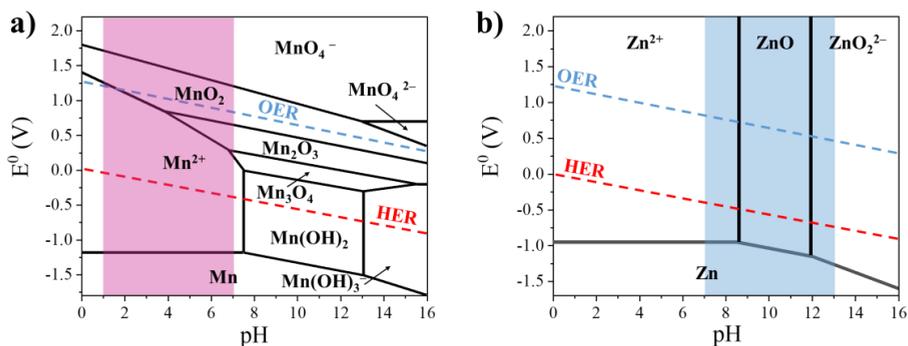

Fig. 1.3. Pourbaix diagrams with marked water decomposition potentials: a) for manganese compounds, and b) for zinc compounds [116].

### 1.3. Dual/amphoteric electrolyte Zn-MnO<sub>2</sub> batteries

To combine the beneficial properties of both alkaline and acidic aqueous electrolytes, a new type of cell has been developed, enabling an increase in the water decomposition voltage above 2 V. The structure of this cell consists of two electrolytes with different pH mediums, allowing the Zn anode to operate in an alkaline electrolyte while the MnO<sub>2</sub> cathode functions in an acidic electrolyte. This unique battery design, whose operating principle is illustrated in Fig. 1.4,

enhances the open-circuit voltage (OCV) of the cell up to 2.45 V, according to Reactions (8)–(10) [54], [113], [114].

Overall reaction:

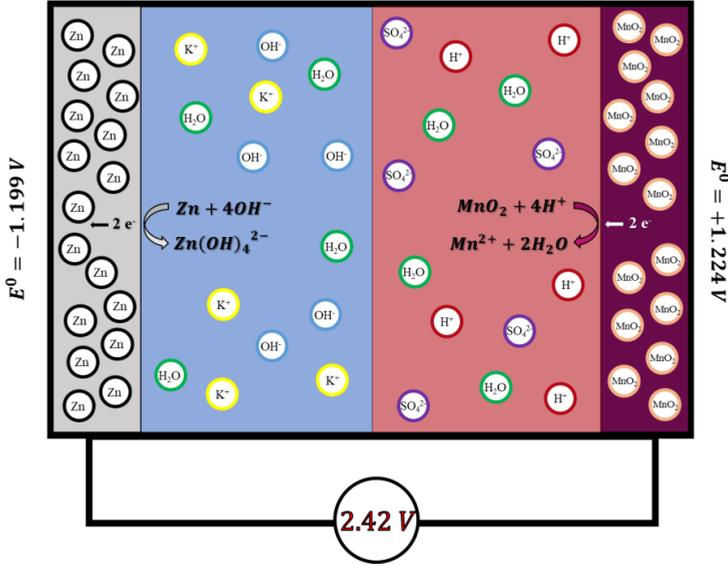

Fig. 1.4. Schematic operating mechanism of Zn-MnO<sub>2</sub> batteries with dual/amphoterous aqueous electrolyte.

The expanded water decomposition voltage window can also be explained using the Pourbaix diagram. As shown in Fig. 1.5, when the battery cell consists of a single electrolyte with a constant pH, the water decomposition voltage is 1.23 V. Consequently, using an aqueous electrolyte battery within a wider voltage window can lead to undesirable OER and HER. However, by employing a dual/amphoterous electrolyte system, it is possible to achieve a stable electrochemical voltage window for the aqueous electrolyte exceeding 2 V. Moreover, considering that, according to the Tafel equation, hydrogen evolution on Zn exhibits a high overpotential [117], [118], while oxygen evolution has a high overpotential [56] and slow reaction kinetics [119], the usable voltage range of the aqueous electrolyte can be extended up to 3 V.

Overall, the concept of a dual-electrolyte system and an expanded water stability voltage window has been described since 2005 [55]–[57]. Later, this dual-electrolyte concept was also applied to various battery systems, including Al-air [120]–[123], Zn-air [121], [124], [125], Mg-air [121], [126], Zn-PbO<sub>2</sub> [127]–[129], Zn-Br<sub>2</sub> [130], and Zn-MnO<sub>2</sub> [54], [58], [131].

However, the operational lifespan and efficiency of all these batteries are limited by neutralization reactions and ion diffusion within the electrolyte.

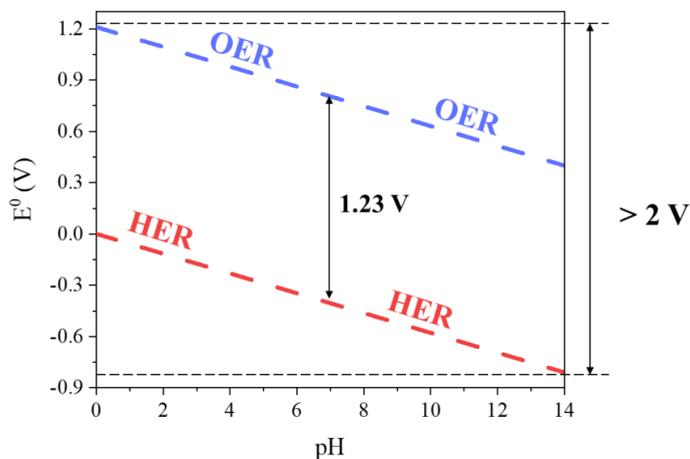

Fig. 1.5. Water Pourbaix diagram [116].

## 2. Main results about the improvement of $\text{MnO}_2$ cathode performance in acidic electrolyte

This chapter describes the improvement of  $\text{MnO}_2$  cathode performance in a highly acidic ( $\text{pH} < 2$ ) aqueous electrolyte by doping  $\text{MnO}_2$  with Bi and Mo ions. The effect of the dopant ions is evaluated by investigating the impact of Bi and Mo ion concentration on the structural and electrochemical properties of  $\text{MnO}_2$ , with concentrations ranging from 0 mol% to 10 mol%. Additionally, the mechanical role of Bi and Mo in stabilizing  $\text{MnO}_2$  during the charge-discharge cycles is also examined.

### 2.1. Methodology

Bi- and Mo-doped  $\text{MnO}_2$  powders were synthesized via a hydrothermal method using  $\text{KMnO}_4$  as the manganese precursor.  $\text{BiCl}_3$  was used as the bismuth precursor and introduced in concentrations ranging from 0 mol% to 10 mol%, while  $\text{Na}_2\text{MoO}_4$  was used for Mo-doped samples in concentrations from 0 mol% to 5 mol%. The required salts for each synthesis were dissolved in distilled water, with a fixed amount of CB additionally introduced. The resulting solution was placed in an autoclave and kept in an oven at 120 °C for either 12 h or 24 h. After the hydrothermal synthesis, all obtained powder samples were thoroughly washed with distilled water and dried in an oven at 60 °C for 24 h.

Additionally, a commercially obtained  $\text{MnO}_2$  (in the pyrolusite phase or  $\beta\text{-MnO}_2$ ) sample was studied as a reference for the synthesized samples. To fabricate the cathodes, pyrolusite

and obtained powder samples were mixed with additional CB in a 13 : 5 ratio to improve the conductivity of the cathode. A cathode slurry was then prepared from the powder mixture by adding a polyvinylidene fluoride solution in N-methyl-2-pyrrolidone (NMP) in a 1 : 9 ratio. The resulting slurry was applied onto carbon paper using a doctor blade, followed by NMP evaporation and cutting the electrodes to the required dimensions.

## 2.2. Results

### 2.2.1. Bi-doped MnO<sub>2</sub> cathode

According to the XRD results shown in Fig. 2.1 a, the synthesized samples exhibited a two-phase mixture consisting of  $\delta$ -MnO<sub>2</sub> (Mn<sub>7</sub>O<sub>13</sub>·5H<sub>2</sub>O – birnessite) and  $\alpha$ -MnO<sub>2</sub> (K<sub>2-x</sub>Mn<sub>8</sub>O<sub>16</sub> – hollandite). Additionally, at higher dopant concentrations, the formation of a BiOCl phase was observed. Increasing the Bi ion concentration in the samples resulted in a decrease in the intensity of the  $\delta$ -MnO<sub>2</sub> phase peak at 24.6° and an increase in the intensity of the  $\alpha$ -MnO<sub>2</sub> phase peaks at 29° and 42°. This suggests that the introduction of Bi ions promotes the formation of the  $\alpha$ -MnO<sub>2</sub> phase, which exhibits a 2 × 2 tunnel-like crystal structure. In this case, Bi ions occupy the vacant sites in the MnO<sub>2</sub> 2 × 2 tunnel structure as a filler. This prevents MnO<sub>2</sub> from adopting the layered  $\delta$ -MnO<sub>2</sub> structure [70], [72], [132]–[134]. The formation of the tunnel-like  $\alpha$ -phase is preferable in this context, as its tunnel structure facilitates ion transport through the crystal lattice, thereby enhancing electrochemical kinetics. In contrast, MnO<sub>2</sub> without dopant ions predominantly exhibited a phase more susceptible to dissolution in acidic environments. Scanning electron microscopy (SEM) images of the samples, shown in Fig. 2.1 b, reveal that the synthesized powders consist of aggregates of smaller and larger needle-like structures, which are characteristic of different MnO<sub>2</sub> polymorphs [135]–[137]. In comparison, the pyrolusite reference sample consists of rounded particle aggregates.

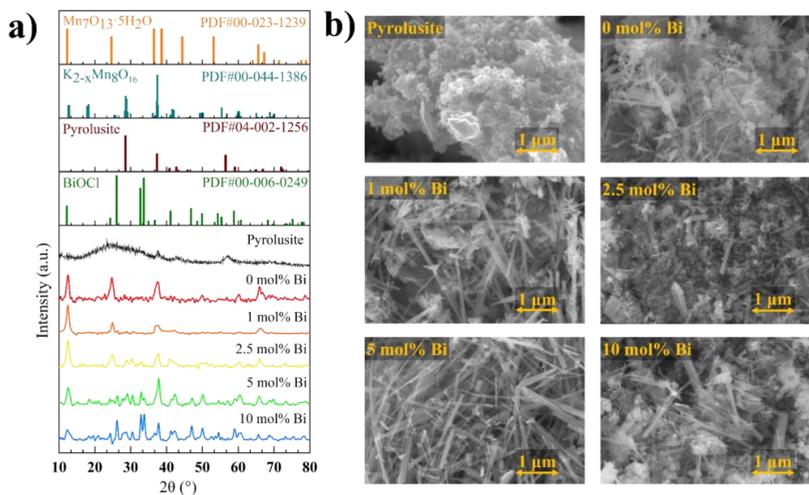

Fig. 2.1. Bi-doped MnO<sub>2</sub> sample and pyrolusite: a) XRD diffractograms, and b) SEM images.

To further characterize the synthesized samples, X-ray photoelectron spectroscopy (XPS) analysis was performed. In the normalized Mn 2p XPS spectra (Fig. 2.2 a), a peak shift towards the Mn<sup>3+</sup> binding energy is observed, which becomes more pronounced with increasing Bi<sup>3+</sup> concentration in the sample. Additionally, the differential spectra of the normalized XPS signals (Fig. 2.2 b) show a decrease in the Mn<sup>4+</sup> signal and an increase in the Mn<sup>3+</sup> signal as the Bi<sup>3+</sup> concentration increases. Similar observations regarding the formation of Mn<sup>3+</sup> and Mn<sup>4+</sup> oxidation states under comparable synthesis conditions in various metal oxide systems have been reported in the literature [138], [139]. These studies explain the role of heteroatoms introduced into the MnO<sub>2</sub> crystal structure in stabilizing metastable Mn<sup>3+</sup> ions, which typically undergo disproportionation in oxide crystal lattices [140]. In the normalized O 1s spectra (Fig. 2.2 c), an increase in hydroxyl groups and adsorbed water on the surface is observed with higher Bi<sup>3+</sup> concentrations in the sample. According to literature data, binding energies in the range of 531–535 eV are closely associated with surface hydroxyl groups, water, or oxygen-containing organic byproducts [141]. Examining the Bi 4f XPS spectra (Fig. 2.2 d), no Bi signal is detected in the 0 mol% Bi sample. However, as the Bi<sup>3+</sup> concentration increases, the Bi signal becomes more pronounced, confirming that all Bi-containing samples have Bi atoms in the 3+ oxidation state [142], [143].

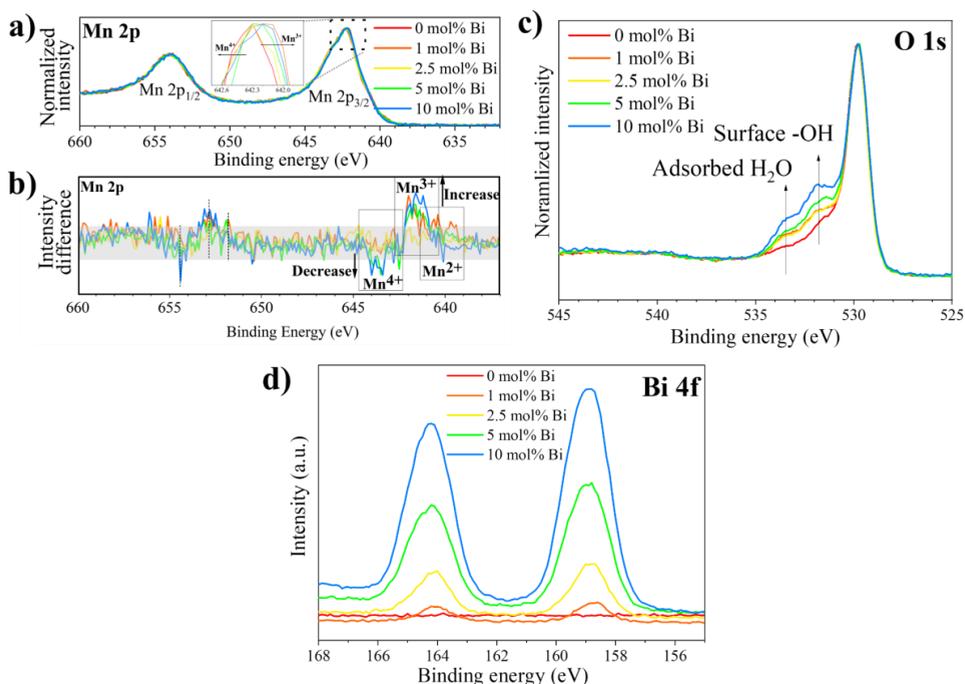

Fig. 2.2. Bi-doped MnO<sub>2</sub> sample and pyrolusite: a) normalized Mn 2p XPS spectra, and b) difference thereof; c) Bi 4f spectra, and d) normalized O 1s spectra.

Cyclic voltammetry (CV) measurements were performed on the prepared cathodes, and the specific capacities of each cathode were calculated based on the obtained data, as shown in Fig. 2.3 a. From these results, at slower scan rates, the cathode with 5 mol% Bi ion content exhibits the highest specific capacity of 130 mAh/g, while the cathode without Bi ions reaches only 120 mAh/g, and the pyrolusite cathode achieves 90 mAh/g.

To evaluate the capacity retention, galvanostatic charge-discharge (GCD) measurements were performed at varying current densities, as shown in Fig. 2.3 b. During the first five cycles, material activation and cathode stabilization take place. The pyrolusite cathode and the cathode without Bi ions require all five cycles to fully stabilize. In contrast, samples containing Bi ions stabilize within 2–3 cycles. In the following 15 cycles, as the current density increases from 0.25 A/g to 1.0 A/g, the pyrolusite cathode exhibits a similar capacity to the cathodes containing 0–5 mol% Bi ions. However, when the current density is reduced back to the initial 0.25 A/g, cathode materials with a higher Bi ion content demonstrate better capacity retention.

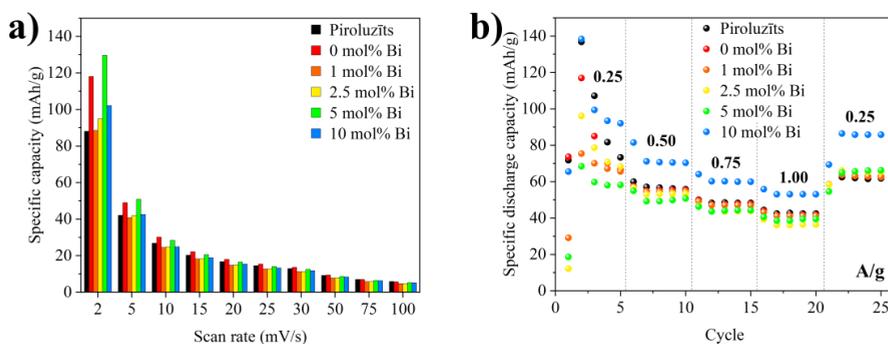

Fig. 2.3. Specific capacities of Bi-doped MnO<sub>2</sub> samples and pyrolusite: a) specific capacities obtained from CV measurements at different scan rates, and b) specific discharge capacities from GCD measurements at different current densities.

The electrochemical impedance spectroscopy (EIS) results for all samples after CV measurements are shown in the EIS diagrams in Fig. 2.4 a, where two compressed semicircles can be observed – one at high frequencies and the other at low frequencies. Additionally, fitted curves are shown based on the equivalent circuit in Fig. 2.4 b. The circuit consists of resistances –  $R_s$ ,  $R_1$ , and  $R_2$  – and constant phase elements –  $CPE_1$  and  $CPE_2$  – parallel to their respective resistances. The values of all these components are listed in Table 2.1. The ohmic resistance of the electrolyte corresponds to component  $R_s$  and is approximately 22–23  $\Omega$  for all samples. The resistance  $R_1$  and constant phase element  $CPE_1$  represent the charge transfer resistance between the electrode and electrolyte as well as the double-layer capacitance. The fitted values indicate that the hydrothermally synthesized cathode materials exhibit a reduced double-layer capacitance, with the most significant reduction observed for the 10 mol% Bi MnO<sub>2</sub> sample. This observation correlates with the increase in surface hydroxyl groups shown in Fig. 2.2 c. The variation in surface hydroxyl group content influences the wetting properties of the

electrode and affects the interaction between the electrode surface and the electrolyte, thereby impacting the charge transfer resistance. The second set of parallel components – resistance  $R_2$  and constant phase element  $CPE_2$  – corresponds to the overall resistance and capacitance between individual cathode particles, since the cathode consists of a mixture of individual semiconductor  $MnO_2$  and CB particles. According to the fitted values, the synthesized samples exhibit significantly lower resistance between individual particles. Comparing the pyrolusite and 0 mol% Bi samples, the CB added during synthesis reduces the particle-to-particle resistance by more than nine times.

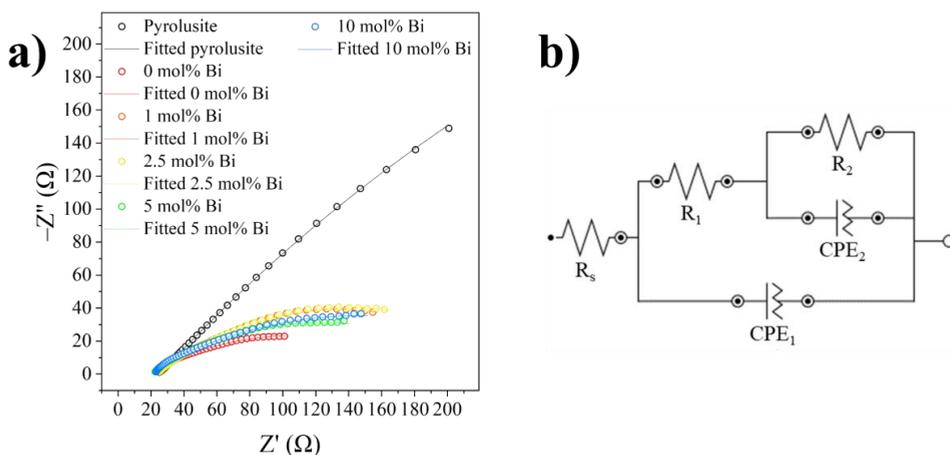

Fig. 2.4. Bi-doped  $MnO_2$  sample and pyrolusite: a) measured EIS diagrams with fitted data according to b) equivalent circuit.

Table 2.1

Equivalent Circuit Parameters of the EIS Fitted Data

Sample	$R_s$ Ω	$R_1$ Ω	CPE <sub>1</sub>		$R_2$ Ω	CPE <sub>2</sub>		$\chi^2$
			$Y^0$	N		$Y^0$	N	
			mS · s <sup>N</sup>			mS · s <sup>N</sup>		
Pyrolusite	23.82	5.05	1.13	0.54	1474.8	1.93	0.52	0.00039

### 2.3.2. Mo-doped MnO<sub>2</sub> cathode

Also, XRD diffractograms shown in Fig. 2.5 for the Mo-doped samples reveal the presence of two phases:  $\delta$ -MnO<sub>2</sub> (Mn<sub>7</sub>O<sub>13</sub>·5H<sub>2</sub>O – birnessite) and  $\alpha$ -MnO<sub>2</sub> (K<sub>2-x</sub>Mn<sub>8</sub>O<sub>16</sub> – hollandite). Similar to the Bi-doped samples, an increase in Mo concentration leads to a decrease in the  $\delta$ -MnO<sub>2</sub> phase and an increase in the  $\alpha$ -MnO<sub>2</sub> phase. This indicates that the addition of Mo dopant promotes the formation of the  $\alpha$ -MnO<sub>2</sub> phase. Additionally, the synthesis time influences the crystallinity of the samples, as evidenced by more pronounced diffraction peaks in the samples synthesized for 24 hours with Mo concentration up to 2.5 mol%. This suggests the formation of larger crystallites [144], which is also consistent with the SEM images shown in Fig. 2.6 a. In these images, the samples synthesized for longer durations exhibit more defined structures, whereas the 12-hour samples consist of randomly shaped agglomerates.

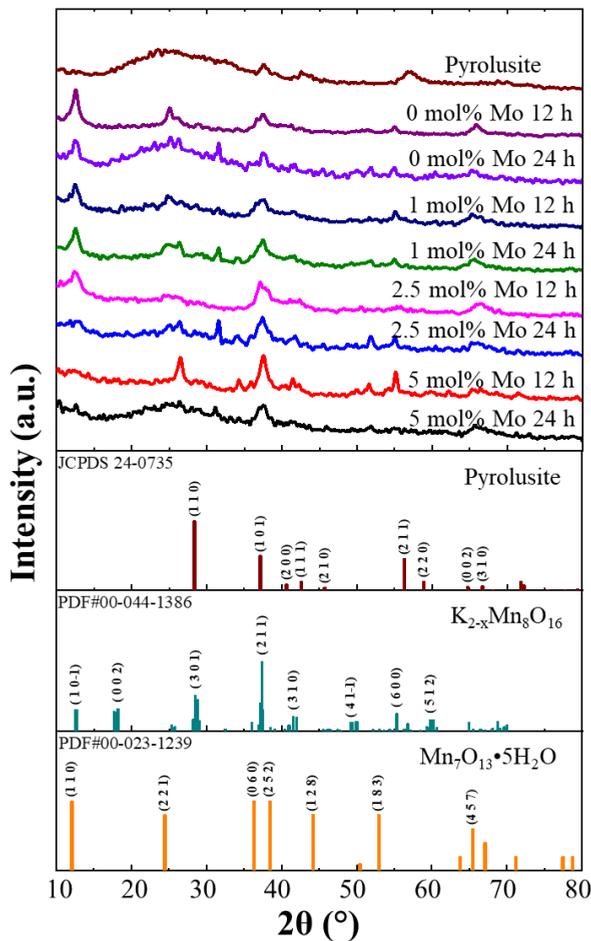

Fig. 2.5. XRD diffractograms of Mo-doped MnO<sub>2</sub> samples and pyrolusite.

XPS analysis was also performed to determine the oxidation states of the elements present, with the spectra shown in Fig. 2.6 b. All samples contain  $\text{Mn}^{4+}$  ions, and the synthesized samples also exhibit carbon-oxygen bonds due to the addition of CB during the synthesis process. Furthermore, the Mo-doped  $\text{MnO}_2$  samples contain  $\text{Mo}^{6+}$  ions and metastable  $\text{Mn}^{3+}$  ions, indicating that the addition of Mo ions also stabilizes  $\text{Mn}^{3+}$  ions [145].

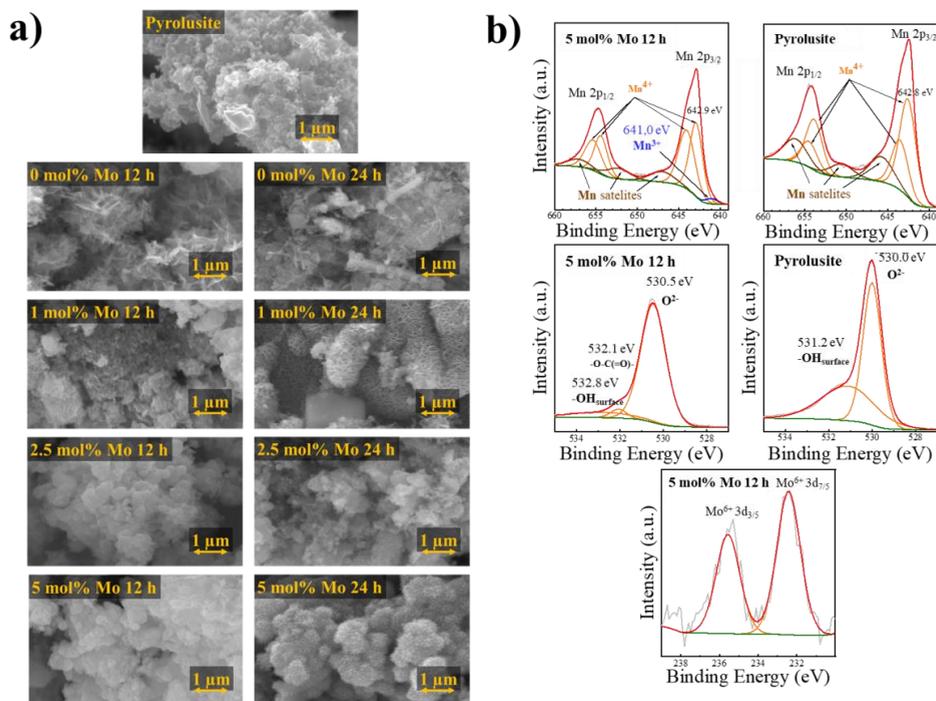

Fig. 2.6. Mo-doped  $\text{MnO}_2$  sample and pyrolusite: a) SEM images, and b) Mn 2p, O 1s and Mo 3d spectra.

Further cathodes were prepared from Mo-doped  $\text{MnO}_2$  samples, and CV measurements were performed to calculate the specific capacities of each cathode, which are summarized in Fig. 2.7 a. All synthesized samples show a higher specific capacity than the pyrolusite sample, with the specific capacity of the synthesized samples increasing as Mo atoms are added. The general increase in specific capacity between the pyrolusite and synthesized samples may be related to phase differences, as seen in the XRD results (Fig. 2.5), where the synthesized samples contain both  $\delta$ - $\text{MnO}_2$  and  $\alpha$ - $\text{MnO}_2$  phases. The highest specific capacity, 415 mAh/g at 0.002 V/s, was obtained from the 2.5 mol% Mo-doped  $\text{MnO}_2$  sample synthesized for 12 hours. However, further tests reveal that the 1 mol% Mo-doped sample, synthesized for 12 hours, retains its specific capacity better as the scan rate increases. Overall, the CV measurements indicate that Mo-doped samples show an increase in specific capacity up to a Mo concentration of 2.5 mol%.

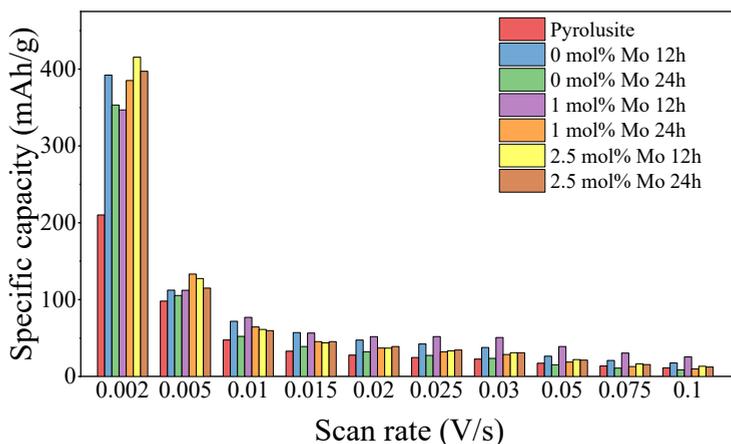

Fig. 2.7. Specific capacities of Mo-doped MnO<sub>2</sub> samples and pyrolusite.

### 3. Main results about improving the performance of the Zn anode in alkaline electrolyte

This chapter describes the improvement of the electrochemical properties of the zinc anode achieved by irradiating the Zn surface with a pulsed laser. The effect of laser irradiation on the structural and morphological properties of the Zn anode was evaluated. The electrochemical properties of the obtained anode materials, such as surface-specific capacity and charge transfer resistance, were examined. Possible mechanisms for the influence of laser modification on the performance of Zn anodes are discussed.

#### 3.1. Methodology

Zinc plates with 99.95 % purity were modified using a nanosecond pulsed Nd: YAG laser at two wavelengths (266 nm and 1064 nm) in air and deionized water environments. A schematic of the irradiation process is shown in Fig. 3.1. The main laser parameters – energy fluence (ranging from 0.32 J/cm<sup>2</sup> to 2.66 J/cm<sup>2</sup>), which varies depending on the irradiation process, and pulse duration (6 ns) – were systematically varied and are summarized in Table 3.1. The resulting Zn anode samples were tested in an electrochemical half-cell with a 1 M KOH electrolyte, a Pt counter electrode, and an Ag/AgCl (3M KCl) reference electrode following surface examination.

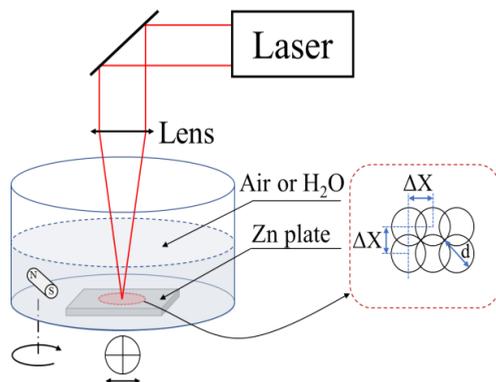

Fig. 3.1. Schematic representation of the laser irradiation process.

Table 3.1

Laser Irradiation Parameters			
Sample*	Laser wavelength, nm	Irradiation medium	Energy fluence, J/cm <sup>2</sup>
Zn	un-irradiated	–	–
Zn-A-2.66*	266	Air	2.66
Zn-A-0.38	1064	Air	0.38
Zn-A-0.59	1064	Air	0.59
Zn-A-0.64	1064	Air	0.64
Zn-A-0.71	1064	Air	0.71
Zn-W-0.32*	266	Deionized water	0.32
Zn-W-0.53*	266	Deionized water	0.53
Zn-W-0.69	1064	Deionized water	0.69
Zn-W-1.29	1064	Deionized water	1.29
Zn-W-1.42	1064	Deionized water	1.42
Zn-W-1.60	1064	Deionized water	1.60

\*A – air medium, W – water medium.

### 3.2. Results

Irradiation of samples with a pulsed laser caused significant morphological changes on the surface, as seen in SEM micrographs (Fig. 3.2). The untreated zinc sample exhibits a smooth surface with cold rolling marks characteristic of the manufacturing process, while the laser-treated samples display various surface morphologies depending on the irradiation environment. Samples irradiated in air with a 1064 nm laser show intense melting during irradiation, resulting in frozen droplet-like structures on the surface. In contrast, samples

irradiated in water with the same wavelength reveal wrinkled structures with homogeneously distributed droplets underneath. Samples irradiated in air with a 266 nm laser exhibit a moderately melted surface with a more uniform texture, whereas irradiation in water induces ZnO growth and forms a wrinkled melt structure.

XRD (Theta/2theta) diffractograms of untreated Zn plates (Fig. 3.3 a) show a polycrystalline Zn pattern with a dominant (002) basal plane parallel to the surface of the sheet. This is related to deformations caused during rolling in the production process [146]. However, Laser treatment of the samples reduces the intensity of the dominant (002) basal plane in the diffractograms. This is due to the surface melting caused by the laser, revealing the underlying polycrystalline structure where the (101) plane dominates. These changes promote more uniform zinc deposition during electrochemical processes. However, Raman spectra shown in Fig. 3.3 b confirm the formation of hexagonal ZnO on the surfaces of the irradiated samples. Additionally, Raman spectra reveal various ZnO defects: oxygen vacancies ( $A_1(LO)$  peak at  $574\text{ cm}^{-1}$ ), interstitial Zn atoms (broad peak between  $250\text{--}300\text{ cm}^{-1}$ ), and nitrogen-related defects (peak at  $275\text{ cm}^{-1}$ ) [147], [148].

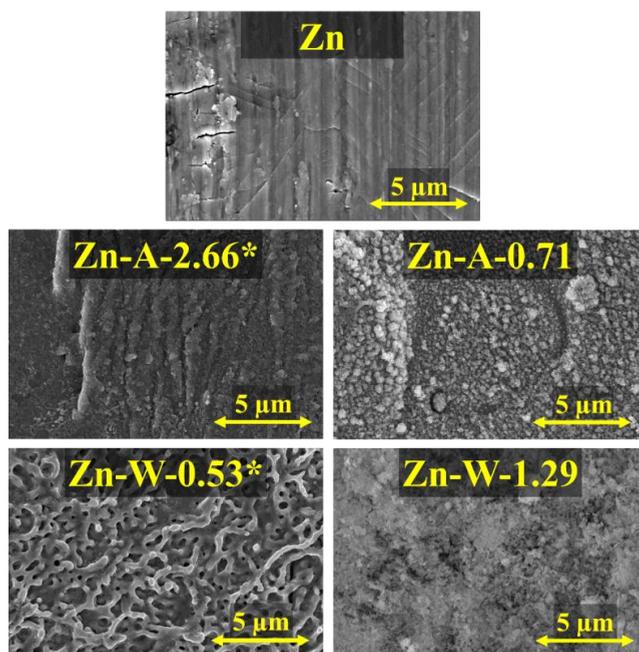

Fig. 3.2. SEM micrographs of untreated and pulsed laser irradiated Zn samples at different energy fluxes (A – in air medium, and W – in water medium).

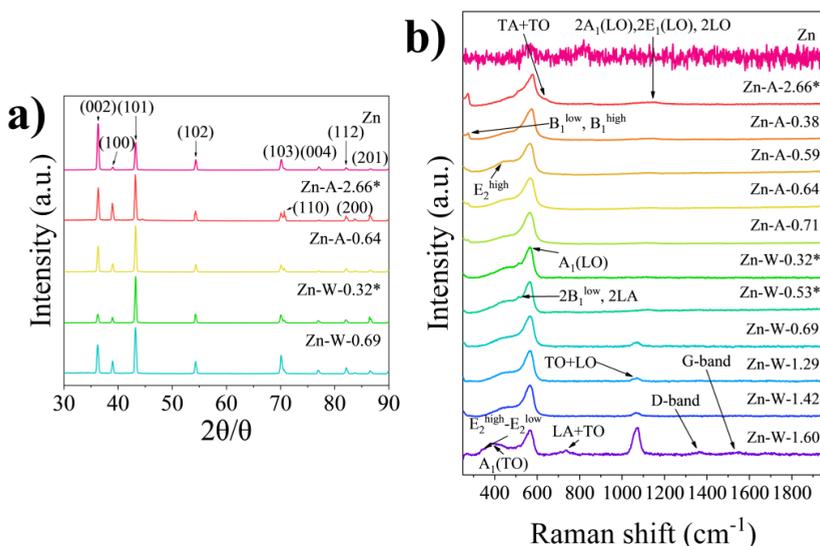

Fig. 3.3. Untreated and laser-irradiated Zn samples: a) XRD diffractograms; b) Raman spectra.

In CV measurements shown in Fig. 3.4 a and b, significant improvements in electrochemical properties are observed for laser-irradiated samples. During anodic oxidation (in accordance with reaction (1)), the Zn sample dissolves electrochemically until the electrolyte can no longer access the active Zn surface for further reaction. During this reaction,  $\text{Zn}(\text{OH})_4^{2-}$  is formed, which immediately turns into ZnO and covers the anode surface. In turn, during the cathodic reduction reaction, a rapid increase in current is observed at  $-1.3$  V [149], [150]. In this potential region, when ZnO is reduced back to Zn, the previously unreacted Zn surface is exposed to the electrolyte. This appears as a sharp current increase, indicating resumed Zn oxidation. Notably, this phenomenon is less pronounced in laser-treated samples, suggesting that oxidation is more controlled and ZnO grows more uniformly, despite that oxidation is at a higher maximum current. This implies that laser surface treatment improves the overall cyclic performance of the Zn electrode, and treated surfaces show higher oxidation and reduction currents, indicating enhanced reaction kinetics.

Specific surface capacities determined from CV measurements are summarized in Fig. 3.4 c and d. At a scan rate of  $0.005$  V/s, samples irradiated in air show slightly higher specific surface capacity ( $1.35$ – $1.50$  mAh/cm<sup>2</sup>) compared to those irradiated in water ( $1.25$ – $1.35$  mAh/cm<sup>2</sup>), and significantly higher than untreated Zn ( $1.15$  mAh/cm<sup>2</sup>). Overall, laser-irradiated samples exhibit an 8–30 % increase in capacity depending on the treatment parameters. This increase is attributed to enhanced surface roughness and more active reaction sites caused by laser-induced melting and re-solidification.

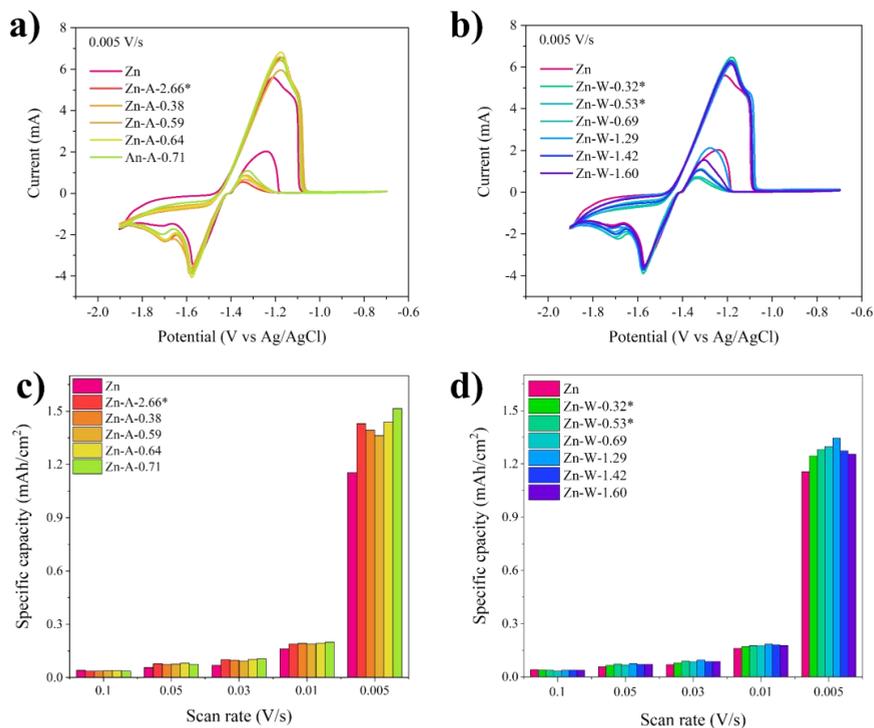

Fig. 3.4. Untreated and air-irradiated Zn samples: a) CV measurements; c) specific surface capacities. Untreated and water-irradiated Zn samples: b) CV measurements; d) specific surface capacities.

After electrochemical measurements, samples were re-examined using SEM (Fig. 3.5) to assess surface changes. The irradiated samples show grain structures with pronounced hexagonal Zn crystal facets. In contrast, the untreated Zn sample surface lacks defined crystal facets and shows random growth features.

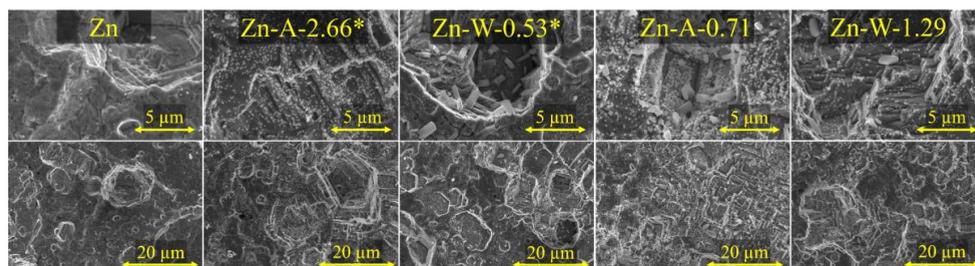

Fig. 3.5. SEM micrographs of untreated and laser-irradiated Zn samples after CV measurements.

Raman spectra of irradiated samples after electrochemical measurements, shown in Fig. 3.6 a, exhibit increased background, and characteristic ZnO peaks are difficult to identify. Conversely, untreated Zn samples still display ZnO peaks at  $382\text{ cm}^{-1}$ ,  $441\text{ cm}^{-1}$  and  $585\text{ cm}^{-1}$ , indicating that laser treatment improves Zn anode electrochemical reactions by promoting more uniform ZnO growth and more complete reversion to metallic Zn. However, untreated Zn samples only undergo partial charging (ZnO reduction to Zn), leading to increased ZnO content and a stronger ZnO Raman signal. This observation correlates with CV results of untreated Zn (Fig. 3.4 a and b), which show a more pronounced phenomenon at  $-1.3\text{ V}$ , linked to increased ZnO formation on the surface.

XRD (Theta/2theta) diffractograms were also repeatedly taken for the sample surfaces after CV measurements, which are shown in Fig. 3.6 b. The untreated Zn sample shows increased intensity of the (002) plane and reduced intensity of the (101) plane, indicating preferential growth in the (002) direction. A slight increase in the (100) plane suggests dendrite-like and porous structure formation [151]. In contrast, irradiated samples retain a polycrystalline (101) structure after CV. An increase in the (002) c-plane direction suggests a more horizontal structure formation. A slight decrease in (100) and (200) plane intensities indicates better resistance to dendrite formation. As illustrated schematically in Fig. 3.6 c, the growth directions of characteristic Zn planes influence potential surface structures. Growth in the (002) plane corresponds to smooth horizontal structures, while growth in (110) and (100) planes indicates dendritic and porous structures.

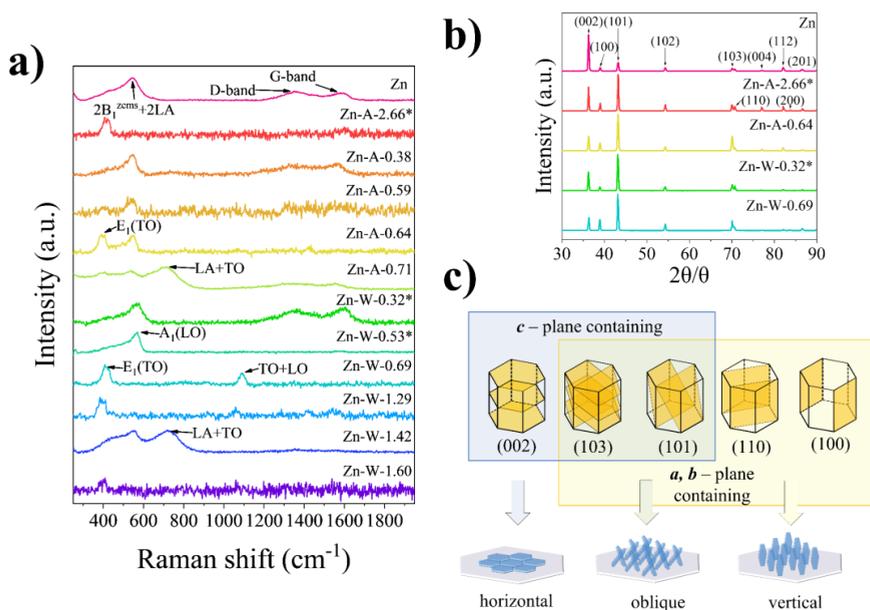

Fig. 3.6. Post-CV measurement results for untreated and laser-irradiated Zn samples: a) Raman spectra; b) XRD diffractograms; c) schematic of hexagonal Zn characteristic crystal planes and growth models.

To further characterize the electrode-electrolyte interface, EIS analysis was performed. EIS spectra at a negative DC offset of  $-150$  mV from OCV are shown in Fig. 3.7 a, and spectra at a positive offset of  $+150$  mV from OCV are in Fig. 3.7 b. Additionally, EIS spectra were fitted using equivalent circuits shown in the graphs, and component values are summarized in Table 3.2. At negative voltage, resistance  $R_1$  is about  $27 \Omega$  for all samples, corresponding to the ohmic resistance of the electrolyte. Resistance  $R_2$  represents the charge transfer resistance of the faradaic process and is lower for laser-treated samples. However, CPE value (representing the double-layer capacitance) is increased for irradiated samples, indicating a macroscopically increased surface area. At low frequencies, all spectra transition into a sloped line, corresponding to Warburg impedance related to diffusion-limited processes.

An extended equivalent circuit model was applied to the obtained EIS diagrams at a positive voltage bias, where Zn oxidation and ZnO formation occur. As before,  $R_s$  represents the electrolyte resistance and is about  $27 \Omega$ . The first  $R_1$  and  $CPE_1$  parallel connection characterizes the state of the electric double layer:  $R_1$  is the ion polarization resistance, and  $CPE_1$  is the double-layer capacitance. Capacitance values are similar, indicating that the macro-surface does not change during the electrochemical reaction. The second parallel circuit of  $CPE_2$  and  $R_2$  describes the faradaic process, where  $R_2$  corresponds to charge transfer resistance. For untreated Zn, this value is  $38 \Omega$ ; however, for laser-treated samples, it increases to about  $200 \Omega$ . This increase is associated with laser-induced defects, also observed in Raman spectra after electrochemical measurements (Fig. 3.6 a). This increases the charge transfer resistance in the irradiated samples and reduces the reaction rate for Zn oxidation.  $CPE_2$  reflects the Zn oxidation process capacitance and is several orders of magnitude higher than the double-layer capacitance. This decrease in capacitance is related to the slowed reaction due to the increased resistance of irradiated samples.

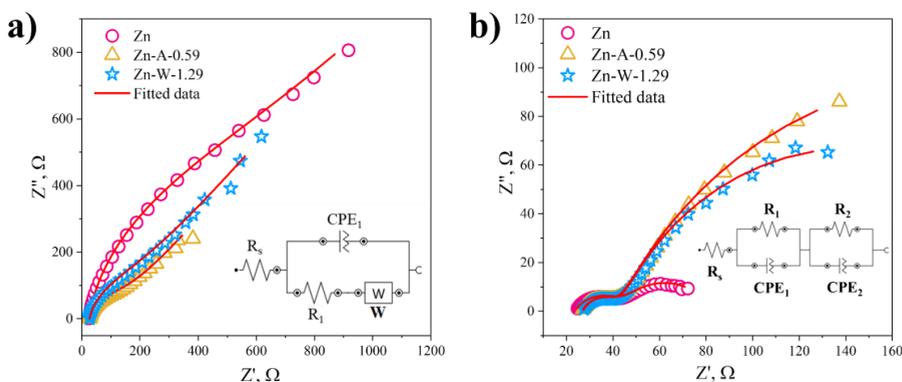

Fig. 3.7. EIS spectra of untreated and laser-irradiated Zn samples: a) at  $-150$  mV DC offset from OCV; b) at  $+150$  mV DC offset from OCV.

Table 3.2

Parameters of the Equivalent Circuit of EIS Fitted Data

Sample	$R_s$	$R_1$	CPE <sub>1</sub>		$R_2$	CPE <sub>2</sub>

#### 4. Main results about the development of amphoteric batteries using hydrogels with different pH environments

This chapter describes the development of an innovatively designed aqueous Zn-MnO<sub>2</sub> battery and the evaluation of its electrochemical properties. The basis of this innovative design is an elevated OCV above that of the commercially available 1.5 V alkaline Zn-MnO<sub>2</sub> battery. This is achieved without the use of membranes, utilizing hydrogel electrolytes with differing pH environments, where the Zn anode is located in an alkaline (KOH) hydrogel electrolyte and the MnO<sub>2</sub> cathode in an acidic (H<sub>2</sub>SO<sub>4</sub>) electrolyte. Additionally, the use of a neutral (K<sub>2</sub>SO<sub>4</sub>) hydrogel as an interfacial layer between the two electrolytes is evaluated. This dual-environment approach minimizes unwanted side reactions, such as Zn anode corrosion in acidic electrolyte and the formation of electrochemically inactive Mn compounds in alkaline electrolyte.

##### 4.1. Methodology

For battery fabrication, 30 wt% Pluronic F-127 micellar solutions were used as electrolytes, dissolved respectively in acidic (0.5 M H<sub>2</sub>SO<sub>4</sub>), alkaline (1 M KOH) and neutral salt (0.5 M K<sub>2</sub>SO<sub>4</sub>) solutions. pH indicators were added to the electrolyte solutions to allow visual identification of pH changes. A Zn plate of defined diameter was used as the anode. The cathode consisted of carbon felt impregnated with a mixture of MnO<sub>2</sub> (pyrolusite phase) and CB in a 13 : 5 ratio, further mixed with the acidic hydrogel to form a homogeneous mass.

To evaluate the performance of each electrode and its corresponding hydrogel, half-cell measurements were performed, where the cathode or anode was the working electrode, one platinum electrode was the counter electrode, and the other platinum electrode was the reference electrode. Afterwards, the battery was assembled in a syringe body (Fig. 4.1), allowing

observation of electrolyte changes during operation. First, the  $\text{MnO}_2$  cathode felt was inserted at the syringe tip, followed by the 0.5 M  $\text{H}_2\text{SO}_4$  acidic hydrogel, the 0.4–0.6 M  $\text{K}_2\text{SO}_4$  neutral hydrogel (only for three-layer batteries), the 1 M  $\text{KOH}$  alkaline hydrogel, and finally the Zn anode, attached to the syringe plunger. In all battery configurations, the total electrolyte volume was fixed at 3 mL.

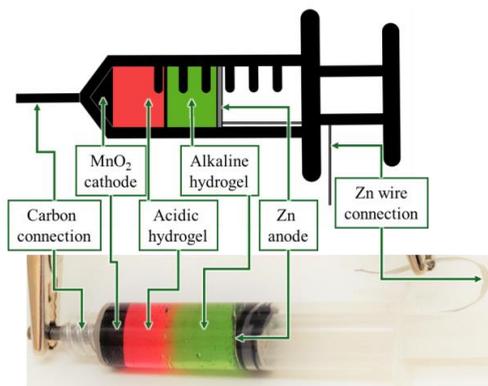

Fig. 4.1. Schematic and photograph of the constructed battery with labelled components.

## 4.2. Results

To determine the theoretical behaviour of the cathode and anode during battery operation, half-cell CV measurements were conducted. The  $\text{MnO}_2$  cathode half-cell with acidic (0.5 M  $\text{H}_2\text{SO}_4$ ) hydrogel and Zn anode half-cell with alkaline (1 M  $\text{KOH}$ ) hydrogel were tested against a Pt counter electrode and Pt reference electrode. According to the combined data shown in Fig. 4.2 a, the OCV of the amphoteric battery is approximately 2.3 V. Measurements from several assembled Zn- $\text{MnO}_2$  amphoteric batteries (Fig. 4.2 a) confirm that the voltage ranges from 2.3 V to 2.4 V.

The expected minimum discharge voltage, based on the combined data, should be around 1.6 V. To assess this theoretical value, a complete discharge of the amphoteric Zn- $\text{MnO}_2$  battery was performed (Fig. 4.2 b) with a discharge current of 10 mA/s. Before discharge, the OCV was 2.4 V, the initial discharge plateau was around 2.0 V, and the end-of-discharge voltage was 1.7 V – consistent with observations from the half-cell CV measurements. Additionally, under a lower discharge current of 0.1 mA/s (Fig. 4.2 c), the initial voltage was 2.34 V, decreasing to 2.2 V over 10 hours.

During all measurements, the formation of a visibly neutral pH layer between the two hydrogels was observed. This can be explained by  $\text{H}^+$  and  $\text{OH}^-$  ion diffusion from the acidic and alkaline electrolytes, where they neutralize in the interface, forming water, further diluting both hydrogel electrolytes and increasing internal resistance. To assess the influence of this neutral layer, OCV measurements were also carried out using an additional neutral hydrogel between the acidic and alkaline layers. The neutral electrolyte concentration ( $\text{K}_2\text{SO}_4$ ) was varied relative to the acid/base concentration at 0.4 M, 0.5 M, and 0.6 M. According to the

measurements shown in Fig. 4.2 d, three-layer hydrogel electrolyte batteries maintained a stable voltage for over 45 h – longer than two-layer batteries, which dropped to 1.7 V after ~ 27 h due to the neutralization reaction. Among the three concentrations, the balanced 0.5 M hydrogel exhibited the longest voltage stability (~ 52 h), while both the lower and higher concentrations maintained stability only up to ~ 45 h. Overall, the pH gradient stability of the three-layer hydrogel electrolyte battery is more pronounced than that of the two-layer system.

To evaluate internal resistances, EIS measurements were performed on a fully assembled amphoteric Zn-MnO<sub>2</sub> battery, and the fitted data according to the equivalent circuit are shown in Fig. 4.3. The obtained parameter values are summarized in Table 4.1. The series resistance  $R_s$  of 30.5  $\Omega$  corresponds to the electrolyte resistance and is relatively high due to limited ion mobility hindered by micellar structures. The first semicircle at high frequencies represents the electrolyte-electrode interface, which is noted in the equivalent circuit as  $R_1$  and  $CPE_1$  parallel connection. Fitted  $R_1$  was found to be 17  $\Omega$ , and the equivalent capacitance of  $CPE_1$  is 102 mF. Both these parameters are sensitive to electrolyte composition [152] and electrode surface porosity [153], [154]. The second semicircle at low frequencies reflects charge-transfer processes, where  $R_{ct}$  is the charge transfer resistance with a fitted value of 6.7  $\Omega$ , and  $CPE_2$  represents the double-layer capacitance with a fitted value of 39 mF.

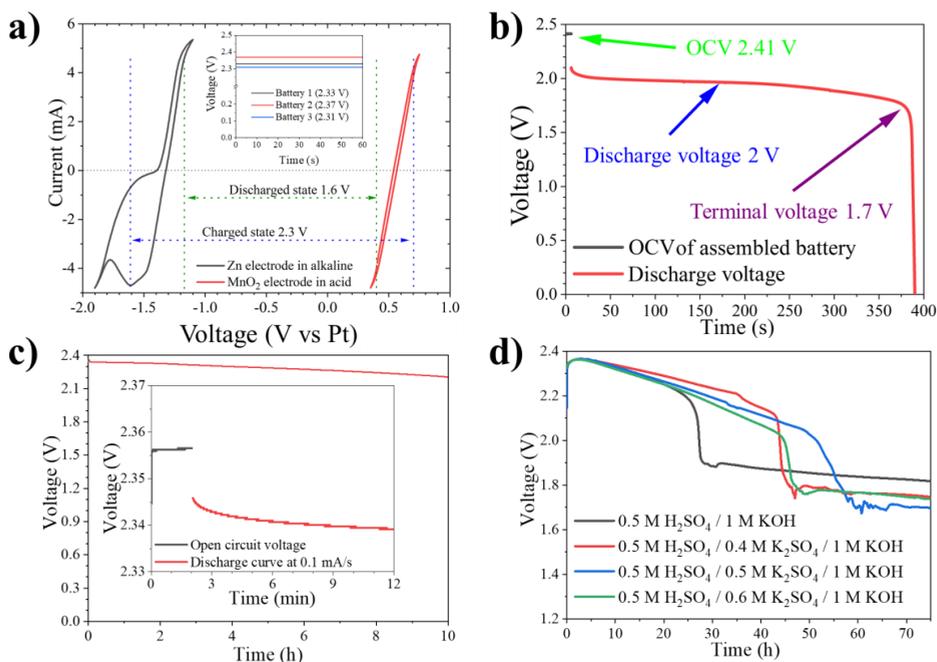

Fig. 4.2. Properties of the amphoteric battery: a) CV measurements of the half-cells in corresponding electrolytes (scan rate 0.01 V/s) and OCV measurements of the prepared batteries; b) OCV and discharge voltage at 10 mA/s discharge current; c) OCV and discharge voltage at 0.1 mA/s; d) OCV measurements for two-layer and three-layer electrolyte batteries with varying neutral layer concentrations.

Table 4.1

Fitted Parameter Values from EIS Measurements Based on the Equivalent Circuit

Parameter	Value	Error, %
$R_s$	30.5 $\Omega$	0.2
$R_1$	17.2 $\Omega$	6
$CPE_1$	106 mF	3
$R_{ct}$	6.7 $\Omega$	7
$CPE_2$	39 mF	4

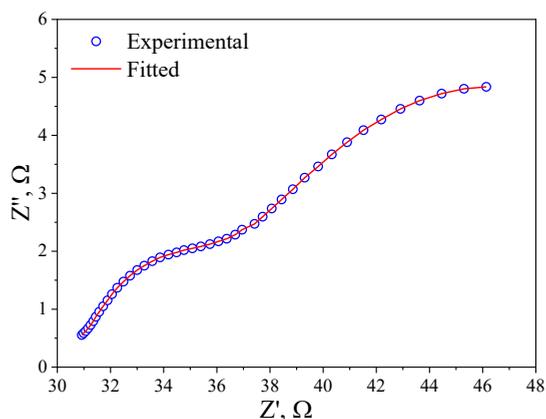

Fig. 4.3. EIS spectrum with fitted model and equivalent circuit.

Chronopotentiometry results for the amphoteric Zn-MnO<sub>2</sub> rechargeable battery with two-layer hydrogels (1 M KOH and 0.5 M H<sub>2</sub>SO<sub>4</sub>) are shown in Fig. 4.4 a, and OCV measurements before discharge, after 100 cycles, and after 200 cycles are shown in Fig. 4.4 b. The upper charge voltage of the battery was around 2.7 V, and the lowest discharge voltage ranged from 2.2–2.3 V. Additional OCV measurements show that the voltage of 2.34 V remained stable throughout 14 hours of cycling. During the measurements, ion diffusion was observed with a visible formation of a neutral pH layer between the hydrogels due to H<sup>+</sup> and OH<sup>-</sup> ion migration and their neutralization, forming water. This further diluted both electrolytes, increasing internal resistance. Additionally, K<sup>+</sup> and SO<sub>4</sub><sup>2-</sup> ions (counterions of the base and acid, respectively, and responsible for ion conductivity) also migrated toward the battery centre, forming crystalline potassium sulphate. This is explained by the limited solubility of K<sub>2</sub>SO<sub>4</sub> in water (120 g/L at 25 °C), further contributing to internal resistance.

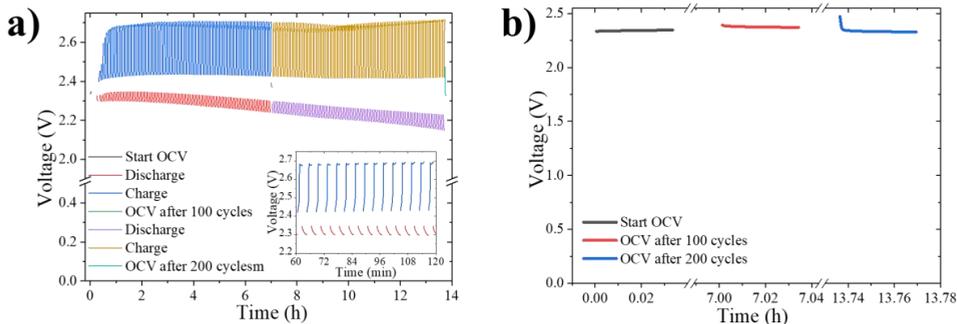

Fig. 4.4. Chronopotentiometry of the two-layer (acidic and alkaline) hydrogel Zn-MnO<sub>2</sub> amphoteric battery: a) charge/discharge curves; and b) OCV before discharge, after 100 and 200 charge/discharge cycles. Charge-discharge current:  $\pm 1$  mA/s.

To assess the effect of the neutral layer in the battery structure, additional chronopotentiometry and OCV measurements were conducted for batteries with a three-layer electrolyte – 1 M KOH, 0.5 M K<sub>2</sub>SO<sub>4</sub> and 0.5 M H<sub>2</sub>SO<sub>4</sub> – shown in Fig. 4.5 a and b. The charge voltage of the three-layer hydrogel battery was 0.5 V higher, and the discharge voltage was 0.5 V lower than in the two-layer battery (Fig. 4.4 a). This charge/discharge voltage discrepancy is due to the higher resistance of the hydrogel electrolyte in the three-layer configuration. While the conductivity of the acidic (0.5 M H<sub>2</sub>SO<sub>4</sub>) hydrogel is 83.6 mS/cm (at 23 °C) and the basic (1 M KOH) hydrogel is 78.6 mS/cm (at 23 °C), the neutral (0.5 M K<sub>2</sub>SO<sub>4</sub>) hydrogel conductivity is more than 6 times lower – 12.6 mS/cm (at 23 °C). This results in a significantly higher total resistance in the three-layer system, causing the observed charge–discharge voltage mismatch. However, the OCV of 2.32 V for the three-layer hydrogel battery (Fig. 4.5 b) remained stable, similarly to the two-layer battery (Fig. 4.4 b).

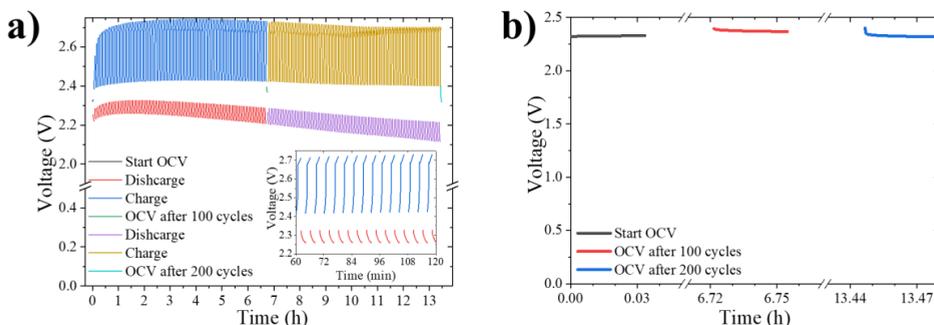

Fig. 4.5. Chronopotentiometry of the three-layer (acidic, neutral, alkaline) hydrogel Zn-MnO<sub>2</sub> amphoteric battery: a) charge/discharge curves; and b) OCV before discharge, after 100 and 200 charge/discharge cycles. Charge-discharge current:  $\pm 1$  mA/s.

## CONCLUSIONS

1. Using a pH gradient electrolyte system, where the Zn anode operates in an alkaline environment, and the MnO<sub>2</sub> cathode operates in an acidic environment, shifts the hydrogen evolution reaction to a lower potential (to -0.81 V) and the oxygen evolution reaction to a higher potential (to +1.2 V), increasing the electrochemical window of water.
2. By doping the MnO<sub>2</sub> cathode with Bi<sup>3+</sup> and Mo<sup>6+</sup> ions, Mn<sup>3+</sup> ions are stabilized in the material, which promotes the formation of the electrochemically more active  $\alpha$ -MnO<sub>2</sub> phase structure. The optimal concentrations have been determined: 5–10 mol% Bi and 2.5 mol% Mo.
3. Irradiating the Zn anode with a pulsed laser increases the specific surface capacity by 30 % and reduces the charge transfer resistance, which improves the kinetics of the electrochemical reaction in a 1 M KOH electrolyte solution.
4. Using Pluronic F-127 micelle hydrogels, a rechargeable amphoteric aqueous electrolyte Zn-MnO<sub>2</sub> battery is obtained, where the Zn anode is in a 1 M KOH electrolyte solution, and the MnO<sub>2</sub> cathode is in a 0.5 M H<sub>2</sub>SO<sub>4</sub> electrolyte solution.
5. The open-circuit voltage of the amphoteric aqueous electrolyte Zn-MnO<sub>2</sub> battery is 2.4 V, the pH gradient stability is maintained for more than 25 hours, the discharge voltage at 0.1 mA/s is 2.34 V, and it is stable for 200 charge–discharge cycles at 1 mA/s.

**Ramona Zukule** (née Dūrena) was born on 18 December 1996 in Limbaži. She obtained a Bachelor's degree in Chemical Technology (2019) and a Master's degree in Nanomaterials Technologies (2021) from Riga Technical University (RTU). Since 2021, she has been pursuing doctoral studies at RTU, focusing on water-based zinc–manganese dioxide ( $\text{Zn-MnO}_2$ ) batteries, their electrolyte modifications, and electrode stabilization mechanisms. From 2022 to 2024, she was a researcher at RTU and participated in the FLPP project "Investigation of electrodes and electrolytes for obtaining amphoteric decoupled rechargeable batteries." She has also worked at the Institute of Solid State Physics, University of Latvia, and since February 2025, has been a patent attorney assistant at AAA Law Latvia Ltd. Her scientific interests are related to the development of water-based  $\text{Zn-MnO}_2$  batteries, the study of electrode-electrolyte interactions, and the application of nanomaterials in electrochemical systems.
